ACKNOWLEDGEMENTS - Section 1

An entry fee is charged corn companies for each hybrid entered to help defray the cost of conducting these corn performance trials and preparing the printed report. Special credit is due the farm cooperators and others for providing land and performing extra operations needed in conducting these trials: Paul Kummer, Colfax; Earl Stover, Larimore; Northern Great Plains Research Center, Mandan; and Walter Albus at the Oakes Research Site. Credit is also due the County Agricultural Extension Agents of the counties involved. The author wishes to express his appreciation for assistance to Brent Bernstein, Shannon Dahl, Sandy Franckowiak, Steve Hanson, Bridget Mugan, Eike Peterson, Theresa Strickland, Steve Tucker, and Marianne Demko who helped collect the data. Special thanks is due Duane Wanner for his valuable assistance in obtaining useful data and coordinating this report.

Entry forms for entries in the hybrid corn performance trials conducted by the main station can be obtained by writing to Dr. Harold Cross, Loftsgard Hall, North Dakota State University, Fargo, ND 58105.

ACKNOWLEDGMENTS - Section 2

Data reported in this section were collected under the supervision of the following personnel at each of the research centers. Blaine Schatz, assistant agronomist, Carrington Irrigation Research Center; Ben Hoag, Superintendent, North Central Research Center, Minot; Neil Riveland, associate agronomist, Williston Research Center; Bryan Hanson, assistant agronomist, Langdon Research Center; Eric Eriksmoen, assistant agronomist, Hettinger Research Center; and Thomas J. Conlon, superintendent, Dickinson Research Center.

Entry forms for entries in these trials can be obtained by contacting these individual research centers.

INTRODUCTION

The average planted corn acreage for North Dakota for the five year period 1985-1990 was 840,000 acres. About 60% of these acres were harvested for grain, and 40% for silage and forage. This represents a higher proportion of grain acres than in past periods. The 1990 estimated corn acreage was 870,000 acres planted with a predicted grain yield of 75 bushels per acre on 600,000 acres harvested for grain according to the USDA Agricultural Statistics Service.

While corn acreage has declined in North Dakota from a peak five year average of 1,344,200 acres in 1959, the total corn grain production (38,605,000 bu.) for the most recent five years (1985-1989) exceeded that of any previous six year period prior to 1982-1986 when production was 39,139,000 bu. Major yield increases coupled with moderate increases in acreage were responsible for this record production (Fig. 1).

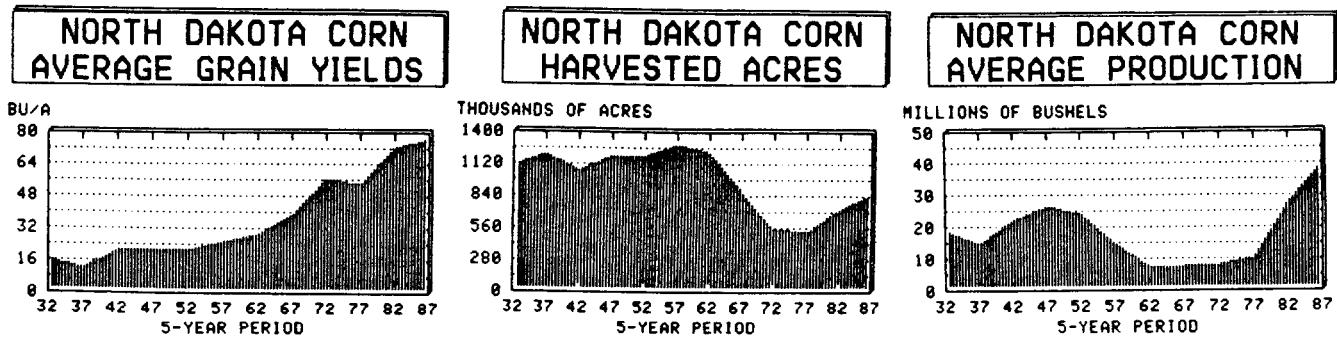

Fig. 1. North Dakota five year average corn yields, harvested acres, and grain production from 1932 to 1988.

North Dakota is about the northern limit of corn grown for grain and silage production which places the basis for selection of a hybrid not only on yield performance but also on agronomic performance, especially maturity. The seed companies and their dealers provide helpful information concerning maturity range and performance of their hybrids, however, the Hybrid Corn Performance Trials are conducted by NDSU in several crop production areas and provide a comparison of many commercial hybrids within each of these areas. Hopefully, these comparisons are of value to seedsmen and farmers in the selection of hybrids which are best adapted to particular crop production areas. The maturity of a particular hybrid is influenced by seasonal temperatures, length of the frost-free period, and cultural practices. The hybrids are ranked by maturity at each of the trial areas on the basis of ear moisture content at harvest. The Hybrid Corn Performance Trials have been conducted for 52 years. Within this 52 year period, corn was well matured in 29 years, reached fair maturity in 14 years, and was immature at harvest in 9 years.

THE 1990 GROWING SEASON

Early spring moisture was barely adequate at most test sites to achieve good seedling emergence. Below normal temperatures in May slowed early seedling development. However, above normal rainfall and temperatures at all test sites in June promoted plant development, and plots generally recovered from the slow early spring growth. Rainfall was much below normal in July and most dryland plots experienced moderate to extreme drought stress. The below average temperatures during this period prevented complete dessication of the dryland plots. Timely rains in July and August at the Larimore and Colfax plots produced yields which were average or slightly above average at those sites. Rather extreme drought stress occurred at Fargo and Mandan which reduced yields at Fargo and completely eliminated ear formation at the Mandan site. Below average precipitation and above average temperatures in September and October produced favorable harvesting conditions and permitted the grain to dry rapidly in the field producing high test weights.

The rainfall and temperature reports as recorded by the nearest climatic station maintained by the National Weather Service are presented in Table 1. In most cases the data are from stations within a few miles of the test site.

Table 1. 1990 Temperature and precipitation data at each of five trial locations.

DEGREE DAYS

The Degree Days concept was developed to measure the amount of heat needed for normal corn growth and maturity, and it relates plant growth to the air temperature. Since corn grows very slowly or not at all below 50 F, this was chosen as the base temperature. The optimum temperature for corn growth is near 86 F, but higher temperatures are of little additional value and may be detrimental to growth. Therefore, 86 F was chosen for the high temperature cutoff point, for the calculation of Degree Days.

In calculating Growing Degree Days (GDD) temperatures from a lower limit of 50 F and an upper limit of 86 F are accumulated by applying the following formula to each day's maximum and minimum temperatures.

$$GDD = \frac{\text{Max. Temp.} + \text{Min. Temp.}}{2} - \text{Base Temp.}$$

Maximum temperatures higher than 86 F are entered as 86 and temperatures below 50 are entered as 50 in the calculations based on daily temperatures.

Table 2. Growing degree day accumulations as compared to the 1970-1989 average values.

MEASURING PERFORMANCE

Corn ear moisture at harvest and silking data are good indicators of maturity. The hybrids are ranked in order of increased ear moisture content in tables dealing with grain yields. The dry matter percentage in the green forage at harvest in the silage trials is also a measure of maturity and the hybrids are ranked in descending order of dry matter accumulation in tables dealing with forage yields. Corn hybrid choices by each grower should be made with regard to maturity as well as yield performance. Other considerations in addition to maturity and yield must be kept in mind. Lodging, plant breakage, and ear height all may contribute to the total harvest yield by facilitating a more efficient harvest and a better quality crop. Test weights also give some information on grain quality. Test weights were taken on dry grain.

In a favorable season, the later maturing hybrids generally yield more than the earlier hybrids but they usually contain more moisture at harvest. Corn grown for grain must mature to produce maximum yield, therefore, early maturing hybrids should be grown for grain production in the cool, short growing season in North Dakota. Corn grown for silage may be slightly later in maturity than that grown for grain but the kernels should be starting to dent at silage harvest. Corn plants should contain 30-35% dry matter at harvest to produce good silage.

Performance of a hybrid may vary from year to year and location to location. A good way to reduce risk from such unstable performance is to plant several hybrids which have demonstrated good performance at the nearest one or more test sites during the past one or two seasons. Planting several hybrids may allow an earlier harvest since some of the hybrids will require less time to reach a harvestable moisture content.

Since the pedigrees of commercial hybrids are not public knowledge, experimental open pedigree hybrids are included in the trials to provide information on their adaptability to growing conditions in the various areas and to provide reference standards in rating commercial hybrids. The pedigrees of the station hybrids included in this year's trials are listed in Table 4.

DESCRIPTION OF TRIAL AREAS

Trial locations are selected to represent the different maturity zones as shown on the corn maturity zones as shown on the corn maturity zone map (Fig. 2).

E.C. - East Central Area, 85 to 92 R.M. zone, Agricultural Experiment Station, Cass County, NDSU, Fargo, Grain and Silage Trial.

S.E. - Southeastern Area, 92 to 102 R.M. zone, Paul Kummer, Colfax, Richland County, Grain Trial.

OKS. - Oakes Irrigated, 92 to 102 R.M. zone, NDSU Research Site, Oakes, Dickey County, Grain Trial.

N.E. - Northeastern Area, 83 to 85 R.M. zone, Earl Stover, Larimore, Grand Forks County, Grain Trial.

W.C. - West Central Area, 80 to 83 R.M. zone, Northern Great Plains Research Center, Mandan, Morton County, Grain Trial.

METHOD OF TESTING

Yields shown are averages of replicated plots grown in a randomized, complete block or lattice experimental designs. The seed corn is planted at an excessive rate and the seedlings thinned to a desired stand. Stands and plot data are reported in Table 3. The yields are based on perfect or nearly perfect stands. Actual plant populations are reported in the various tables. One of the objectives of these trials is to determine the inherent performance of the hybrid entry rather than its seed quality.

Grain yields are reported in bushels of shelled corn per acre at 15.5 percent moisture. Plots were harvested with a plot combine, except at Oakes where plots were hand harvested. Grain was weighed, dried, and reweighed to determine moisture content.

Silage yields are reported in tons of silage per acre at 70 percent moisture. The entire plant is harvested except the extreme basal stem part. The ears were husked and removed from the stalk, weighed, and dried separately. Ears were shelled and weighed to determine grain percentage in the silage. The grain contains most of the carbohydrate in a corn plant and this determination is a reflection of silage quality for feeding purposes. A sample of the corn stover was chopped and dried to determine the dry matter percentage at harvest which is a measure of maturity.

Stalk lodging and root lodging counts were taken on all trials except Oakes. Root lodging and stalk lodging are reported as the percentage of ear-bearing stalks which were lodged 30 degrees or more from vertical or broken below the ear at harvest, respectively. Lodging is based on an average of all replications. Silking dates taken at Oakes were the average dates when 50% of the plants had silks emerged.

Variations in soil fertility, moisture, and other cultural or environmental factors are found in each test area which make it difficult to compare the yielding ability of hybrids with absolute accuracy. Hence, small differences in yield have no meaning. A statistical measure known as the LSD or Least Significant Difference is an aid in determining the significance of a yield difference observed between two hybrids. If the difference observed is greater than the LSD .05 value at the bottom of the table, the chances are greater than 20 to 1 that it is a real difference and not due to chance alone. If the difference is greater than the LSD .01 value the chances that a true difference exists is greater than 100 to 1.

Helping You Put Knowledge To Work

NDSU Extension Service, North Dakota State University of Agriculture and Applied Science, and U.S. Department of Agriculture cooperating. William H. Pietsch, Director, Fargo, North Dakota. Distributed in furtherance of the Acts of Congress of May 8 and June 30, 1914. We offer our programs and facilities to all persons regardless of race, color, sex, religion, age, national origin, or handicap; and are an equal opportunity employer.
