SOYBEANS are an important cash crop in North Dakota. In 1961, 199,000 acres were harvested.

Soybeans were first grown mainly in southeastern North Dakota, which is also the commercial corn area. This area is best suited to soybean production because of its favorable temperatures, longer growing season and generally satisfactory rainfall. Soybeans for seed harvest are now grown as far north as the Canadian border in the eastern counties.

Soybeans are a long season crop and need favorable moisture throughout the summer and early fall. This limits their westward expansion in the state.
SOIL PREFERENCE

Soil requirements for soybeans are about the same as for corn. A mellow, fertile, medium-textured loam soil will usually be best. Heavier soils should have good drainage. Sandy loam soils warm up faster and, when adequate rainfall is available, will hasten development of soybeans in a cool or short growing season.

A soil relatively free from weeds is very desirable to avoid serious weed competition. Effective weed control is important in obtaining profitable soybean production.

CHOOSING THE VARIETY

Choose a variety of soybeans which will mature under the average local growing conditions and produce a satisfactory yield of high-quality beans. In general, the farther north or west in North Dakota, the earlier the variety you need.

Suggested soybean varieties, based on corn maturity zones (Fig. 1), are listed here for North Dakota. Your location within any one zone, or your own experience, should be considered in selecting from the several varieties suggested. Table 1, listing Experiment Station yields and other crop data at the Fargo station along with the maturity classification listed may help you in selecting the variety to grow.

VARIETIES SUGGESTED FOR CORN MATURITY ZONES

Soybean varieties suggested for each of the state's corn maturity zones (Fig. 1) are listed in Table 1, in order of maturity. The earliest are at the top and the later maturing ones toward the bottom.

1/ See map, Fig. 1, corn maturity zones.
2/ Acme shatters easily and must be harvested as soon as ripe.
3/ 1959 data omitted due to hail.

The yield figures above indicate only slight yield differences among the several varieties best adapted to the area. If you are now planting a variety adapted to your area, cultural practices such as early planting and weed control will affect yield more than selection of another variety.

INOCULATION

Soybean seed should be inoculated with "soybean bacteria" before planting. This provides the necessary bacteria in the soil which will allow the soybean plants to function as a legume, utilizing and storing nitrogen from the air. This inoculant is different from that required for alfalfa, sweet clover and other legumes.

SEEDBED PREPARATION

Soybeans respond to good seedbed preparation. On fall plowed fields shallow spring tillage to kill weeds before planting is effective. On soils where spring plowing is practiced, plowing is usually done just before planting time. A firm, moist seedbed, as
free from weed seed as possible, is desired. The sooner soybeans are planted after the last cultivation the better their chance to compete with the weeds.

**FERTILIZING**

Soybeans do best in fertile soil but have been rather erratic in their response to commercial fertilizer. If a soil test of the field or response in other crops indicates distinctly low phosphate availability, a row application by planter attachment of 5 to 10 pounds of nitrogen and 20 to 40 pounds of phosphate is recommended.

Fertilizer results have varied considerably, so experience on your farm is your best guide. Leave an unfertilized check strip for comparison. Fertilizer should be applied in a band along the row to prevent possible injury to the seed.

**PLANTING**

Soybeans should not be planted until the soil has warmed up and air temperatures are favorable. This usually is about corn planting time. This slightly delayed seeding allows time to kill early starting weeds before planting.

On good land where weeds are not a serious problem, planting as early as favorable conditions permit allows the beans to take advantage of the entire growing season and results in higher yields. Four-year data from “date-of-planting” studies made at the Fargo Experiment Station show that plantings made after the middle of May have resulted in lower seed yield, poorer seed quality, lower oil content, shorter plant height, pod set closer to the ground and more lodging. Late planting may be justified where weed control is of prime importance.

Planting in rows is the most common method used and permits cultivation for weed control which is important in obtaining good yields. A corn planter with the proper plates, a grain drill, or a sugar beet planter, may be used. Plant about 1-1/2 to 2 inches deep to place the seed in moist soil. Planting too deep, or in a soil which crusts, may result in poor emergence.

The most common row spacing is 40 to 42 inches, the same as for corn. This makes it possible to use regular corn planter and cultivator equipment. Experiment Station results at Fargo show
that row spacings narrower than 36 inches have not given higher yields except for short, or early maturing varieties and for all varieties when planted late (after June 1). Such narrow rows will require special planting and cultivating equipment.

Close drilled, or solid, seedings will produce satisfactory yields only if the land is relatively free from weeds. Some weed control early in the season can be obtained with a harrow or rotary hoe, but, if there are very many weeds in the field, weed control is often unsatisfactory.

**RATE OF SEEDING**

In 40 to 42-inch plantings for best yields and competition with weeds, plant soybeans about 1 to 1-1/2 inches apart in the row. This takes about 45 to 60 pounds of live seed per acre, depending on the row spacing and size of seed. There are about 3,000 medium-sized soybeans in 1 pound. For 20 to 24-inch row spacing about 90 to 100 pounds of seed per acre are required. Seed about 120 pounds per acre for solid seedings. In all cases adjust the seeding rate for size of seed and germination test.

**WEED CONTROL**

Effective weed control is important in obtaining high soybean yields. Start weed control early. A rotary hoe, spike-tooth harrow or weeder can be used between plantings and before emergence of the beans.

When the beans are 3 to 8 inches tall, frequent cultivations with a rotary hoe, light harrow or weeder are very effective in killing weed seedlings in the rows with little damage to the beans. Do this when the beans are slightly wilted during the warm part of the day.

Row plantings can be cultivated with ordinary corn or beet cultivators. Two or three cultivations are usually needed. Shallow cultivation with sweep-type cultivator shovels is recommended to prevent ridging, which makes harvesting more difficult, and to prevent serious injury from root pruning. Avoid cultivating soybeans when the leaves are wet to prevent the possibility of spreading diseases which may be present.

Selective chemical weed control in soybeans is not recommended. Pre-emergence chemicals have been erratic and unde-
pendable in North Dakota. If you wish to try them, the following pre-emergence chemicals are suggested: For annual grasses (except wild oats) Randox at 4 to 5 pounds active ingredient per acre. For annual grass and broadleaf weeds, Amiben at 2 to 4 pounds active ingredient per acre, or Alnap at 4 pounds active ingredient per acre. Band application can be used to reduce the cost per acre. Soybeans are somewhat susceptible to injury from 2,4-D or MCPA and drift onto soybean fields should be avoided.

**HARVESTING**

Straight combining is the most satisfactory and commonly used method of harvest. It is important to follow the combine manufacturer’s recommendations for necessary adjustments to prevent splitting and breaking the beans. Cylinder concaves or bars should be opened up as required and cylinder speed reduced by about one-half. If the beans are very dry it may be necessary to combine only in the morning or evening when humidity is high.

Harvest soybeans when the plants mature and the beans are dry, containing not more than 14 per cent moisture. When very dry (8 to 10 per cent moisture) more shattering and injury to the seed in harvesting will generally occur. Shattering of about 40 beans per square yard represents a loss of 1 bushel per acre.

**STORING**

Soybeans may be stored safely for short periods of time during the fall or winter with a moisture content as high as 14 per cent. For safe storage during the spring or summer months soybeans should not contain more than 12 per cent moisture. Beans free of foreign material and split beans store better and stay in condition longer.
